ABSTRACT

A rotorcraft including a fuselage, one or more motor-driven
rotors for vertical flight, and a control system. The motors
drive the one or more rotors in either of two directions of
rotation to provide for flight in either an upright or an inverted
orientation. An orientation sensor is used to control the pri-
mary direction of thrust, and operational instructions and
gathered information are automatically adapted based on the
orientation of the fuselage with respect to gravity. The rotors
are configured with blades that invert to conform to the direc-
tion of rotation.

INVERTIBLE AIRCRAFT

This application is a Continuation application of International PCT Application No. PCT/US2012/000160, filed Mar. 22, 2012, which claims the benefit of U.S. Provisional Application No. 61/465,705, filed Mar. 22, 2011, each of which is incorporated herein by reference for all purposes.

The present invention relates to an aircraft configured to fly and hover in either an upright or inverted orientation with respect to gravity, and to a related rotor with invertible blades.

BACKGROUND OF THE INVENTION

A common and dangerous task for friendly personnel (e.g., military personnel or police) is clearing all or part of a building. This typically entails killing, capturing, or forcing the withdrawal of all enemy personnel (e.g., enemy combatants or criminals) in the building, while preventing innocent bystander casualties and other collateral damage. At some point in the act of clearing a building, a first squad of friendly personnel must enter a first room the building. This activity may involve significant personal risk to the first squad. One way to lower this risk is to detonate a hand grenade, or other injury causing or incapacitating device, in the room prior to entry. Nevertheless, such a device can harm innocent bystanders and/or cause significant damage to property.

Unmanned aerial vehicles (UAVs) and unmanned ground vehicles (UGVs) have been developed for a large array of tasks. One such UAV task is for aerial reconnaissance. For example, the Raven® UAV, with a wingspan over 4 feet, provides low-altitude surveillance and reconnaissance intelligence for both military and commercial applications. Nevertheless, typical UAVs are not sized and configured for indoor flight in the crowded and complex settings typically encountered while clearing a building, and getting a UAV into a building could prove problematic in dangerous situations. Moreover, if a typical UAV were used indoors, it would be difficult for it to recover from any accidental encounter with an object that interrupted its flight and made it fall to the ground.

UGVs have been suggested for use in clearing buildings. Nevertheless, UGVs sized for indoor use would not provide good viewing angles, such as might be needed to identify enemy personnel hiding in ambush behind barriers. Furthermore, they are not configured to handle the array of obstacles (e.g., stairs) that a typical indoor surveillance device could encounter.

Accordingly, there has existed a need for an unmanned vehicle capable of being used for surveillance in a crowded, indoor environment. There has also existed a need for methods of gathering intelligence for clearing a room or building using such devices. Preferred embodiments of the present invention satisfy these and other needs, and provide further related advantages.

SUMMARY OF THE INVENTION

In various embodiments, the present invention solves some or all of the needs mentioned above, providing an unmanned vehicle capable of being used for surveillance and gathering intelligence in a crowded, indoor environment, and related methods.

A UAV rotorcraft under the present invention may include a fuselage, one or more rotors, one or more motors configured to drive the one or more rotors in rotation, and a control system. The fuselage defines a vertical dimension (i.e., with respect to the fuselage), and the rotors are generally oriented

for vertical thrust (i.e., thrust along the vertical dimension with respect to the fuselage). The control system is configured to control the speed with which the one or more motors drives the one or more rotors in rotation.

Advantageously, the one or more motors are configured to drive the one or more rotors in either of two directions of rotation, and the control system is configured to control the one or more motors such that it can change a primary direction of thrust (with respect to the fuselage) developed by the one or more of rotors by reversing their direction of rotation. As a result, the rotorcraft can take off and fly in either an upright or an inverted orientation with respect to gravity. The rotorcraft is therefore not incapacitated if it becomes inverted.

An advantageous feature of the rotorcraft is that the control system may be configured to control the primary direction of thrust with respect to the fuselage based on the orientation of the fuselage with respect to gravity. Moreover, the rotorcraft may include an orientation sensor configured to sense the orientation of the fuselage with respect to gravity. Thus, the control system may be configured to control the primary direction of thrust with respect to the fuselage based on a signal from the orientation sensor and without active instruction from a remote operator of the rotorcraft.

A further advantageous feature of the rotorcraft is that the control system is configured to adapt its coordination of the rotors speeds, and to adjust the signals from all directional sensors (i.e., sensors generating data that is orientation sensitive) based on the primary direction of thrust with respect to the fuselage (i.e., based on the orientation of the fuselage with respect to gravity). Thus, operational instructions and gathered information can be provided without consideration of the orientation of the fuselage (i.e., upright or inverted) with respect to gravity.

Other features and advantages of the invention will become apparent from the following detailed description of the preferred embodiments, taken with the accompanying drawings, which illustrate, by way of example, the principles of the invention. The detailed description of particular preferred embodiments, as set out below to enable one to build and use an embodiment of the invention, are not intended to limit the enumerated claims, but rather, they are intended to serve as particular examples of the claimed invention.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a top view of a quadrotor UAV embodying the present invention.

FIG. 2 is a front cross-sectional view of the quadrotor UAV of FIG. 1, taken at line 2-2 of FIG. 1, flying in an upright orientation.

FIG. 3 is a front cross-sectional view of the quadrotor UAV of FIG. 1, taken at line 2-2 of FIG. 1, flying in an inverted orientation.

FIG. 4 is a schematic diagram of portions of the quadrotor UAV of FIG. 1 and a ground station for the quadrotor UAV of FIG. 1.

FIG. 5 is a cross-sectional view of a blade of the quadrotor UAV of FIG. 1, taken at line 5-5 of FIG. 3.

FIG. 6 is a partial perspective view of an alternative version of a rotor for the quadrotor UAV of FIG. 1.

FIG. 7 is a perspective view of a thruster including a motor, a blade inversion mechanism and a rotor for one embodiment of the quadrotor UAV.

FIG. 8 is a first schematic view of the thruster of FIG. 7.

FIG. 9 is a second schematic view of the thruster of FIG. 7.

FIG. 10 is a perspective view of variation of the thruster of FIG. 7.

3

FIG. 11 is a perspective view of another embodiment of a thruster including a motor, a blade inversion mechanism and a rotor.

FIG. 12 is a process diagram for a method embodying the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

The invention summarized above and defined by the enumerated claims may be better understood by referring to the following detailed description, which should be read with the accompanying drawings. This detailed description of particular preferred embodiments of the invention, set out below to enable one to build and use particular implementations of the invention, is not intended to limit the enumerated claims, but rather, it is intended to provide particular examples of them.

Generally, embodiments of a UAV under the present invention reside in a hover-capable UAV having one or more (and typically a plurality of) vertically oriented rotors (i.e., a rotorcraft). The UAV is configured to reverse the thrust direction of one or more of the rotors to adapt it to the orientation of the UAV with respect to gravity. Preferred embodiments of the invention are quadrotor UAVs that include orientation sensors, and a control system configured to seamlessly (i.e., without requiring any user input or adaptation) change the thrust direction of each rotor to adapt to the UAV's orientation, and to adapt all command data and received sensor data accordingly.

The present invention provides for a UAV that, among other tasks, can provide for comparatively safe and civilian-friendly clearing of a building by friendly personnel (e.g., military personnel or police). In a military action of clearing a building, at some point a first squad of soldiers must enter a first room the building. This activity may involve significant personal risk to the soldiers. One way to lower this risk is to detonate a hand grenade in the room prior to entry. Unfortunately, that hand grenade can harm innocent civilians and/or cause significant damage to an innocent civilian's property.

Under a method of the invention, instead of a hand grenade, a small, remotely controlled UAV is delivered (e.g., tossed) into the room prior to the soldiers' entry into the room. Using the UAV, a pilot (typically being another of the soldiers) flies the UAV around the room and uses a video camera on the UAV to check for the presence of enemy personnel, explosives and other traps. Optionally, the UAV may be flown from room to room to further check for dangers prior to the soldiers' entry. The UAV can also either land on something, or affix itself to a surface such that it hangs from the surface without using rotor activity to maintain its position, such that it can serve as a security camera with a view (position and orientation) providing the soldiers' with ongoing intelligence of developing situations, and thus better security.

One problem with using a small quad rotor UAV for this is procedure is that the UAV, when it is first tossed into the room, might land in an upside-down (i.e., inverted) orientation. Another problem is that during flight, the UAV might be knocked to the floor (either by inadvertently running into something or being batted down), and end up in an inverted orientation. This later risk is particularly relevant when flying through rooms with hanging objects (e.g., lights, fans and plants). In either case, a typical UAV, when inverted, would be effectively immobilized with no way to right itself (i.e., to turn itself upright). A UAV under the preferred embodiment can adapt to being inverted and proceed accordingly.

With reference to FIGS. 1 to 4, a UAV 101 under a first embodiment of the invention is a quadrotor that defines an

4

upright orientation (see, e.g., FIG. 2) with respect to gravity 91, i.e., it defines a vertical dimension 93 and an upward direction 95 with respect to the fuselage that is opposite the direction of gravity when the fuselage is in the upright orientation. The quadrotor also defines an inverted orientation (see, e.g., FIG. 3) with respect to gravity 91 in which the upward direction 95 with respect to the fuselage is in the same direction as gravity.

The UAV 101 includes a body serving as a central fuselage 103, and four propulsion arms 105 extending laterally from a proximal end 107 that is connected to the fuselage, to a distal end 109. The UAV also includes four electric motors 111. Each motor is attached to the distal end of a respective propulsion arm. Each motor has a rotor 113 that is configured to be driven in rotation by the motor in an orientation (i.e., a rotational direction) that causes vertically downward thrust 115 with respect to gravity when the UAV is in the upright orientation with respect to gravity (see, e.g., FIG. 2). The combination of the motor and the rotor form a thruster configured to provide thrust in a primary direction of thrust with respect to the fuselage, i.e., along the vertical dimension.

The fuselage 103 includes a power source such as a battery 121, a flight control system 123, and a sensor system 125 that includes a camera 127 and an orientation sensor 129. The control system is configured to control the speed with which the motors drive the rotors in rotation. It is further configured to reverse the direction of rotation of the rotors, and thus the motors are configured to drive the rotors in either of two directions of rotation.

The control system is configured, i.e., programmed, to coordinate the operation of the rotors to accomplish controlled flight in response to a flight controller, as is known for quadrotor aircraft. This may be done in response to manual instructions sent by a flight controller in the form of a remote operator (such as is known for remote control vehicles operated by people) who is operating a ground station 131 configured with a processor 132, a display 133 to display a video feed from the UAV camera 127, manual controls 135, a wireless transceiver 137, and a power source such as a battery 139.

The manual controls 135 are human operated controls for manual flight, which may be in the form of an electronic or electromechanical device such as a game controller or standard remote control transmitter. The ground station wireless transceiver 137 is configured to communicate via a wireless connection 141 with a UAV wireless transceiver 143 to send the operator's high-level flight control inputs to the UAV flight control system 123, and to receive information (such as a video feed) back from the UAV camera 127. Alternatively, high-level flight control inputs may be generated in response to automated instructions within the flight control system in the form of a preset and/or adaptive control program. This control program may use input from other sensors 145 such as a signal from a GPS (Global Positioning System) sensor.

Typically, these instructions (whether manual or automated) will be directed to high-level flight instructions (e.g., fly higher, fly forward, turn, and the like) and payload instructions (e.g., turn on the camera, pan the camera, and the like). The control system 123 is adapted to convert the high-level instructions into low-level instructions, such as instructions that activate individual motors to actuate their rotors at the desired rotor rotation rates and in the desired directions, or instructions that control the power delivered to the motors to accomplish that same purpose.

In the present embodiment, during typical flight all of the rotors 113 will be creating thrust in the primary direction of thrust with respect to the fuselage 103. That primary direction of thrust will be in the vertical dimension 93, and will be

5

either in a downward direction **97** or the upward direction **95** with respect to the fuselage. At any given time during flight, for flight control reasons, it is possible that one or more of the rotors could be directed to reverse its thrust direction (without changing the primary direction of thrust of the UAV). This ability can add to the agility and maneuverability of the UAV, and/or assist it in conducting unusual maneuvers, such as to free itself from an entanglement.

The control system **123** is further configured to control the one or more motors **111** such that it can change the primary direction of thrust with respect to the fuselage (developed by the rotors) between the upward direction **95** and the downward direction **97**. The primary direction of thrust is changed based on the orientation of the rotorcraft fuselage with respect to gravity. Such a change is normally done prior to takeoff. This may be done manually, i.e., at the direction of a remote operator observing the camera and manipulating the manual controls **135**, or by the control system **123** based on a signal from the orientation sensor **129**. Thus, the UAV can adapt its primary direction of thrust based on its orientation. The primary direction of thrust might also be changed during flight for a rapid, powered descent, should one be needed.

The control system **123** is further configured to adapt its coordination of the rotor speeds and directions based on the primary direction of thrust (which is based on the orientation of gravity). In other words, the low-level instructions vary based on the orientation of the aircraft such that high-level instructions such as fly up and forward can be made without consideration of the orientation of the UAV **101** with respect to gravity.

The UAV camera **127** has a field of view, which may be static with respect to the fuselage, or movable via an actuator. Thus, the camera is a directional sensor configured to sense the external environment, and provides a video feed for display on the display **133**, allowing an operator to control the UAV, and providing useful information to the operator (such as the presence of dangers to personnel in the vicinity of the UAV). The control system **123** is configured to adjust the signal of this directional sensor (and any other onboard directional sensors) based on the primary direction of thrust. Thus, a remote operator or a person reviewing the sensor data will view the information (e.g., the video feed) in a correct orientation with respect to gravity without having to take any manual procedures to correct the orientation. In other words, if the UAV is flying upside down, the control system automatically flips the picture so it is right side up when viewed by the operator.

In a variation of this embodiment, the UAV **101** could deliver an uncorrected sensor stream (e.g., a video feed not corrected for the orientation with respect to gravity), along with an orientation signal (from the orientation sensor **129**) indicating the orientation of the UAV with respect to gravity. The orientation signal may be continuously sent, or may be sent at the initiation of each flight. The ground station **131** would then be configured to correct the orientation of the information displayed on the display **133** based on the orientation signal (which is in turn based on the orientation of the UAV with respect to gravity).

With reference to FIGS. **1** to **5**, each rotor **113** of the UAV has a plurality of blades **151** that extend longitudinally out from a hub **153** along a longitudinal blade axis **157**, and blade guard **155** surrounding the path through which the blades rotate. The longitudinal axis is normal to the cross-sectional view of FIG. **5**. The blade guard protects people and things near the UAV from being hit by a blade. At the same time, the

6

blade guard guards against things becoming entangled in the rotor, and against the rotor being inadvertently stopped when the UAV strikes something.

In a first blade embodiment, and contrary to well accepted practice, the rotor blades **151** are not configured as airfoils in which the camber is different (e.g., larger) near a leading edge than near a trailing edge (as is typical for propellers and rotors). Instead, the blade is characterized by a 2-fold symmetry along the longitudinal blade axis (i.e., the cross section of the blade looks no different when rotated 180° around the longitudinal blade axis. As a result, each blade is configured to produce equal thrust in either direction of rotation for a given rotational speed.

With reference to FIG. **6**, in a variation of the blade for the embodiment, each blade camber could be configured to be adaptable based on the direction of rotation of the rotor. In one version, each blade includes a section of sailcloth **201** that extends between two relatively rigid frame elements **203** that extend out from a rotor hub **205**. The frame elements are offset from one another such that with the sailcloth hung loosely, the sailcloth will bow out during rotation of the rotor. As a result, when the rotor rotates in a first rotational direction **211**, the sailcloth will bow out in a shape adapted to produce thrust in a first thrust direction **213**. When the rotor rotates in the opposite rotational direction, the sailcloth will bow out in another shape that is adapted to produce thrust in the opposite thrust direction.

With reference to FIG. **7**, in another blade embodiment, blades **501** are configured with an efficient camber and shape for producing thrust in one direction, as is well known for aircraft propellers and helicopter rotors. To adapt to being used in either of two rotor rotational directions, the rotor is configured with a blade inversion mechanism **503** that rotates each blade around its own longitudinal blade axis **505** such that the blade can be oriented in two positions that are substantially 180 degrees apart. The blade is thereby adjustable to be oriented in the correct direction to create efficient thrust in either direction (i.e., up or down with respect to the rotorcraft, in other words, down with respect to gravity). The blades are adjustably oriented based upon the direction the rotor is rotating, which in turn is based on the orientation of the rotorcraft with respect to gravity.

In this embodiment, the two blades **501** are mounted on a blade shaft **507** that extends along the blade axes **505** of both blades. Rigidly mounted on the blade shaft is a circular gear **509** (in the form of a spur gear) forming a gear plane that is normal to the blade shaft and the blade axes. The motor is within a motor housing **511**, and is configured to rotate a motor shaft **513** with respect to the motor housing around a motor axis of rotation **515**. The blade inversion mechanism **503** includes an inversion disk **521**, a support **523**, a first stop **525** and a second stop **527**. The support, the first stop and the second stop are each attached to the inversion disk.

The inversion disk is a flat, circular disk that is rotationally symmetric around the motor axis of rotation **515** and forms a drive surface **529**. The inversion disk **521** is rigidly attached to the motor shaft **513** with the drive surface normal to the motor axis of rotation. Imprinted into the drive surface **529** of the inversion disk **521** is a circular track of teeth **531** concentrically encircling the support **523**, effectively forming the inversion disk into an inversion gear **533** in the form of a crown gear.

The support **523** is restrained by the inversion disk **521** such that it is held in place with respect to the inversion disk, but can freely rotate around the motor axis of rotation **515** with respect to the inversion disk. The blade shaft **507**, in turn, is restrained by the support **523** such that the blade shaft is

7

held in place with respect to the support, but can freely rotate around the blade axes **505** with respect to the support. The circular gear **509** has a plurality of teeth **535**. The circular gear teeth **535** are in contact with the inversion gear teeth **531** such that the circular gear **509** is meshed with the inversion gear **533**.

As a result of this configuration, the blades **501**, blade shaft **507** and support **523** can freely rotate around the motor axis of rotation **515** with respect to the inversion disk **521**. When the blades, blade shaft and support rotate around the motor axis of rotation with respect to the inversion disk, the inversion gear **533**, which is meshed with the circular gear **509**, drives the blades and the blade shaft in rotation around the blade axes **505** with respect to the support **523**.

The first and second stops **525**, **527**, are rigidly affixed to the inversion disk **521** on opposite sides of the support **523**. They extend up into the path of the blade shaft **507** as it rotates around the motor axis of rotation **515** with respect to the inversion disk, providing first and second limits to the range of positions through which the blade shaft can rotate with respect to the inversion disk. While this function could be accomplished by a single stop, it is preferable to use two in order to keep the rotor rotationally balanced around the motor axis of rotation **515**. Alternatively, other balancing mechanisms may be used to rotationally balance the rotor.

At the first limit to the range of positions through which the blade shaft can rotate with respect to the inversion disk **521**, the blades are oriented for efficient thrust in a first direction **541** parallel to the motor axis of rotation **515**. At the second limit to the range of positions through which the blade shaft can rotate with respect to the inversion disk, the blades are oriented for efficient thrust in a second direction **543** parallel to the motor axis of rotation **515**. The first and second directions are opposite one another. The orientation of the blades **501** around the blade axes **505** while in the first position, is substantially 180 degrees from the orientation of the blades around the blade axes while in the second position, with respect to the support.

The first and second stops **525**, **527** are magnetic, and the blade shaft **507** is composed of a ferromagnetic material. As a result, when the blade shaft is in the first position the magnets will apply a force attempting to hold it in the first position. Likewise, when the blade shaft is in the second position the magnets will apply a force attempting to hold it in the second position.

When initially activated, the motor will apply a rotational force around the motor axis of rotation **515** to the inversion disk **521**, causing it to spin. Because the blades **501** and blade shaft **507** can rotate around the motor axis of rotation, with respect to the inversion disk, the rotational inertia of the blades and blade shaft around the motor axis of rotation **515** will cause the inversion disk to rotate with respect to the blades and blade shaft. The force of the motor is greater than the restraining force of the magnets, so the blade shaft will pull away from the magnetic stops if the blade shaft is in the wrong limit position around the motor axis of rotation.

The meshed gears **509**, **531**, will in turn drive the blades and blade shaft in rotation around the blade axes **505** until the blade shaft reaches the appropriate limit position (either the first or second limit of the range of positions through which the blade shaft can rotate around the motor axis of rotation) with respect to the inversion disk. The magnetic nature of the stops with the blade shaft at the newly reached limit position will limit the blade shafts from bouncing off of the stops as the blade shaft reaches the new position.

At that limit position, the first and second stops will drive the blades and blade shaft in rotation around the motor axis. It

8

should be noted that the blades and blade shaft have a much lower rotational inertia around the blade axis than around the motor axis of rotation, thus leading to the gears causing rotation around the blade axes rather than rotation around the motor axis of rotation.

If difficulties arise from the magnetic stops restraining the mechanism from driving the blade shaft to the appropriate limit position, an additional procedure may be used. In particular, the blades may first be driven in the wrong direction, and then be driven in the appropriate position. The angular momentum of the blades spinning in the wrong direction will then help to break the magnetic hold of the stops on the blade shaft.

FIGS. **8** and **9**, depict the transition of the thruster between then upright orientation (shown in FIG. **8**) and the inverted orientation (shown in FIG. **9**). In a first relative orientation **601**, the inversion disk **521** is rotating in a first direction **603** around the motor axis of rotation (relative to the motor housing), which causes the rotor (including the blades **501** and blade shaft **507**) to rotate in a second direction **605** around the motor axis of rotation, relative to the inversion disk. In this orientation, the blades are positioned for upright flight, and the inversion disk drives the blades in rotation around the motor axis of rotation (relative to the motor housing) to provide upright vertical thrust.

In a second relative orientation **611**, the inversion disk **521** is rotating in a third direction **613** around the motor axis of rotation (relative to the motor housing), which causes the rotor to rotate in a fourth direction **615** around the motor axis of rotation, relative to the inversion disk. The first and third directions of rotation relative to the motor housing are opposite one another. Likewise, the second and fourth directions of rotation relative to the inversion disk are opposite one another. In this orientation, the blades are positioned for inverted flight, and the inversion disk drives the blades in rotation around the motor axis of rotation (relative to the motor housing) to provide inverted vertical thrust.

Many variations of this blade embodiment are within the scope of the invention. For example, in the present embodiment, the first and second positions of the blades and blade shaft are almost 180 degree apart around the motor axis of rotation. If four stops are used (or two stops with additional weights to balance the rotor), a much smaller rotation could be set between the first and second position limits. This could lead to a significantly smaller circular gear as compared to the size of the inversion disk.

With reference to FIG. **10**, other configurations of stops may be used. For example, in a variation of this blade embodiment, blades **701** are again configured with an efficient camber and shape for producing thrust in one direction, as is well known for aircraft propellers and helicopter rotors. To adapt to being used in either of two rotor rotational directions, the rotor is configured with a similar blade inversion mechanism **703** that rotates each blade around its own longitudinal blade axis **705** such that the blade can be oriented in two positions that are substantially 180 degrees apart. The blade is thereby adjustable to be oriented in the correct direction to create efficient thrust in either direction (i.e., up or down with respect to the rotorcraft, in other words, down with respect to gravity). The blades are adjustably oriented based upon the direction the rotor is rotating, which in turn is based on the orientation of the rotorcraft with respect to gravity.

As was the case in the prior variation, in this variation, the two blades **701** are mounted on a blade shaft **707** that extends along the blade axes **705** of both blades. Rigidly mounted on the blade shaft is a circular gear **709** (in the form of a spur gear) forming a gear plane that is normal to the blade shaft and

the blade axes. Mounted on the circular gear is a circular-gear stop having a first magnetic end **726** and a second magnetic end **728**.

The motor is within a motor housing, and is configured to rotate a motor shaft **713** with respect to the motor housing around a motor axis of rotation **715**. The blade inversion mechanism **703** includes an inversion disk **721**, a support **723**, a first inversion-disk stop **725** and a second inversion-disk stop **727**. The support, the first inversion-disk stop and the second inversion-disk stop are each attached to the inversion disk.

The inversion disk is a flat, circular disk that is rotationally symmetric around the motor axis of rotation **715** and forms a drive surface **729**. The inversion disk **721** is rigidly attached to the motor shaft **713** with the drive surface normal to the motor axis of rotation. Imprinted into the drive surface **729** of the inversion disk **721** is a circular track of teeth **731** concentrically encircling the support **723**, effectively forming the inversion disk into an inversion gear **733** in the form of a crown gear.

The support **723** is restrained by the inversion disk **721** such that it is held in place with respect to the inversion disk, but can freely rotate around the motor axis of rotation **715** with respect to the inversion disk. The blade shaft **707**, in turn, is restrained by the support **723** such that the blade shaft is held in place with respect to the support, but can freely rotate around the blade axes **705** with respect to the support. The circular gear **709** has a plurality of teeth **735**. The circular gear teeth **735** are in contact with the inversion gear teeth **731** such that the circular gear **709** is meshed with the inversion gear **733**.

As a result of this configuration, the blades **701**, blade shaft **707** and support **723** can freely rotate around the motor axis of rotation **715** with respect to the inversion disk **721**. When the blades, blade shaft and support rotate around the motor axis of rotation with respect to the inversion disk, the inversion gear **733**, which is meshed with the circular gear **709**, drives the blades and the blade shaft in rotation around the blade axes **705** with respect to the support **723**.

The first and second inversion-disk stops **725**, **727**, are rigidly affixed to the inversion disk **721** on opposite sides of the support **723**. They are positioned such that they respectively block the path of the first magnetic end **726** and a second magnetic end **728** of the circular gear stop as the circular gear rotates around the motor axis of rotation **715** with respect to the inversion disk, providing first and second limits to the range of positions through which the blade shaft can rotate with respect to the inversion disk.

As in the prior variation, at the first limit to the range of positions through which the blade shaft can rotate with respect to the inversion disk **721**, the blades are oriented for efficient thrust in a first direction **741** parallel to the motor axis of rotation **715**. At the second limit to the range of positions through which the blade shaft can rotate with respect to the inversion disk, the blades are oriented for efficient thrust in a second direction **743** parallel to the motor axis of rotation **715**. The first and second directions are opposite one another. The orientation of the blades **701** around the blade axes **705** while in the first position, is substantially 180 degrees from the orientation of the blades around the blade axes while in the second position, with respect to the support.

The first and second inversion gear stops **725**, **727** are magnetic, and the two ends of the circular gear stop are magnetic. As a result, when the blade shaft is in the first position, two of the magnets will apply a force attempting to hold it in the first position. Likewise, when the blade shaft is

in the second position, the other two magnets will apply a force attempting to hold it in the second position.

When initially activated, the motor will apply a rotational force around the motor axis of rotation **715** to the inversion disk **721**, causing it to spin. Because the blades **701** and blade shaft **707** can rotate around the motor axis of rotation, with respect to the inversion disk, the rotational inertia of the blades and blade shaft around the motor axis of rotation **715** will cause the inversion disk to rotate with respect to the blades and blade shaft. The force of the motor is greater than the restraining force of the magnets, so the blade shaft will pull away from the magnetic stops if the blade shaft is in the wrong limit position around the motor axis of rotation.

The meshed gears **709**, **731**, will in turn drive the blades and blade shaft in rotation around the blade axes **705** until the blade shaft reaches the appropriate limit position (either the first or second limit of the range of positions through which the blade shaft can rotate around the motor axis of rotation) with respect to the inversion disk. The magnetic nature of the stops with the blade shaft at the newly reached limit position will limit the blade shafts from bouncing off of the stops as the blade shaft reaches the new position.

At that limit position, the stops will drive the blades and blade shaft in rotation around the motor axis. It should be noted that the blades and blade shaft have a much lower rotational inertia around the blade axis than around the motor axis of rotation, thus leading to the gears causing rotation around the blade axes rather than rotation around the motor axis of rotation.

If difficulties arise from the magnetic stops restraining the mechanism from driving the blade shaft to the appropriate limit position, an additional procedure may be used. In particular, the blades may first be driven in the wrong direction, and then be driven in the appropriate position. The angular momentum of the blades spinning in the wrong direction will then help to break the magnetic hold of the stops on the blade shaft.

In another variation, the rotor could be configured with more than two blades. To do that, separate gearing would likely be provided for each blade, or for each pair of blades. In yet other variations, this blade inversion mechanism could be driven through a variety of other structural arrangements, both using other arrangements of gears and/or other rotational mechanisms. For example, the blade inversion could be driven by a separate motor mechanism that is actively controlled by a control system.

With reference to FIG. 11, in another rotational mechanism, the rotor is driven by cables and/or strings. More particularly, a motor shaft **813** is configured to be driven in rotation around a motor axis of rotation **815** by a motor. A support **823** is concentrically received on the motor shaft, and is configured to freely rotate around the motor axis of rotation with respect to the motor shaft. The support has a support shaft **841** extending laterally in a direction forming a blade axis **805** for a blade **801**. The blade is carried on a blade shaft **807**, which is concentrically received on the support shaft, and is configured to freely rotate around the blade axis with respect to the support **823**.

The blade shaft **807** has first and second arms **843** extending in opposite directions normal to the blade axis **805**. Each arm is provided with a cable **845** that is wrapped around and attached to the motor shaft **813**. The cables of the two arms are wrapped in opposite directions. When the motor shaft rotates in the first direction, a first arm's cable wraps tightly around the motor shaft, while the second arm's cable loosens up. As a result, the tightly wrapped first-arm cable pulls on its arm, causing the first arm to drive the blade to rotate around the

11

blade axis of rotation with respect to the support **823**, and then causing the blade to rotate around the motor axis of rotation. When the motor shaft rotates in a second, opposite direction, the second arm's cable wraps tightly around the motor shaft, while the first arm's cable loosens up. As a result, the tightly wrapped second-arm cable pulls on its arm, causing the arm to drive the blade to rotate in the opposite direction around the blade axis of rotation with respect to the support **823**, and then causing the blade to rotate around the motor axis of rotation in the opposite direction.

It should be noted that the various blade inversion mechanisms are not limited to mechanisms that rotate each blade 180 degrees around its blade axis. If differing amounts of thrust are required in the opposite directions, or if differing environmental conditions exist between the use in one direction and in the other direction, then it might be preferable to rotate to positions a little over or a little under 180 degrees. Moreover, while the two limit positions are generally 180 degrees apart, the blades could be rotated much more to travel between those positions. For example, if a much smaller circular gear is desired with respect to the inversion disk, the gearing could be configured for the blades to rotate 540 degrees (i.e., 180 degrees plus 360 degrees), or 900 degrees (i.e., 180 degrees plus 720 degrees).

It should be noted that the blade inversion mechanism may have significant uses outside of the aircraft arts. For example, a rotor having this blade inversion mechanism could be used for a wide variety of fans ranging from ceiling fans to fans used in a wide variety of industrial applications. Likewise, the blade inversion mechanism may also have marine applications.

With reference to FIGS. **1** to **3**, the embodiment may further include one or more surface-connection devices **301** configured to allow the rotorcraft to affix itself to a surface such that it hangs from the surface, and thus that it does not need rotor activity to maintain the position. Such surface-connection devices may be of a variety of types (e.g., magnets, adhesive devices, hook and latch materials, and suction devices), and their selection will depend on the nature of the environment in which the UAV will operate. The reversibility of the motors can provide for an increased ability of the rotorcraft to break free of such a connection once it is no longer desired. For example, two rotors pushing one way and two pushing the other might provide enough torque to free a hook and latch attachment.

Other embodiments include variations of the above-described information. For example, such embodiments may be based on other numbers of motors and/or rotors, and more generally can be described as having one or more motors, and/or one or more rotors.

With reference to FIG. **12**, a method of gathering intelligence (such as of dangers) prior to entering a room under the invention resides in the steps of 1) delivering **401** (e.g., tossing) a UAV such as the above-described UAV quadrotor into the room, 2) adapting **403** the UAV to have a primary direction of thrust based on the orientation of the UAV with respect to gravity once it has come to rest in the room, 3) instructing **405** the UAV to fly, and 4) scanning **407** the room using a sensor such as the camera to gather intelligence, such as determining the presence of dangers. While these steps will typically be conducted in sequential order (and/or simultaneously for some of the steps), other orders are possible, such as scanning the room prior to flight. Optionally, the method may also include the step of 5) if the flight of the UAV is interrupted prior to the completion of steps (2) through (4) (or

12

before the completion of all the steps if there are more steps), then restarting **411** all the steps from step (2).

Optionally, method may alternatively or further include the steps of 5) instructing **421** the UAV to fly to one or more additional rooms, and 6) scanning **423** the one or more additional rooms, using the sensor, to further gather intelligence, such as determining the presence of additional dangers, prior to entry. Optionally, the method may also or alternatively include the steps of 5) affixing **431** the UAV to hang from a surface in a position and orientation in which the sensor can provide continuing intelligence, such as of dangers, and 6) continuing **433** to scan using the sensor to gather intelligence, such as of developing dangers, from the position in which the UAV is affixed.

It is to be understood that the invention comprises apparatus and methods for designing and for producing UAVs, as well as the apparatus and methods of using the UAV. Additionally, the various embodiments of the invention can incorporate various combinations of these features with existing UAV missions. In short, the above disclosed features can be combined in a wide variety of configurations within the anticipated scope of the invention.

While particular forms of the invention have been illustrated and described, it will be apparent that various modifications can be made without departing from the spirit and scope of the invention. Thus, although the invention has been described in detail with reference only to the preferred embodiments, those having ordinary skill in the art will appreciate that various modifications can be made without departing from the scope of the invention. Accordingly, the invention is not intended to be limited by the above discussion, and is defined with reference to the following claims.

What is claimed is:

1. A rotor for use with a motor with a shaft configured to drive the rotor in either of two opposite directions of rotation, comprising:

one or more blades, each blade having a longitudinal blade axis;

an inversion mechanism configured to rotate each of the one or more blades around the longitudinal blade axis between a first position oriented for efficient thrust in a first direction parallel to the two directions of motor rotation, and a second position oriented for efficient thrust in a second direction parallel to the two directions of rotation of the motor, the first and second directions of thrust being in opposite directions.

2. The rotor of claim **1**, wherein the orientation of each blade around the blade axis in the first position is substantially 180 degrees different from the orientation of that blade in the second position.

3. The rotor of claim **1**, wherein the inversion system includes:

a first gear attached to the blades;

a second gear attached to the motor shaft, wherein the first gear is meshed with the second gear; and

one or more stops configured to limit the relative movement of the first gear with respect to the second gear.

4. The rotor of claim **1**, wherein the inversion system includes a cable affixed to and wrapped around the motor shaft in a configuration that drives the blades to the first position when the motor shaft rotates in the first direction, and that drives the blades to the second position when the motor shaft rotates in the second direction.
